ABSTRACT

VARMA, JYOTHISH S. Scalable, Fault-Tolerant Membership for Group Communication on HPC Systems. (Under the direction of Associate Professor Dr. Frank Mueller).

Reliability is increasingly becoming a challenge for high-performance computing (HPC) systems with thousands of nodes, such as IBM's Blue Gene/L. A shorter mean-time-to-failure can be addressed by adding fault tolerance to reconfigure working nodes to ensure that communication and computation can progress. However, existing approaches fall short in providing scalability and small reconfiguration overhead within the fault-tolerant layer.

This thesis presents a scalable approach to reconfigure the communication infrastructure after node failures. We propose a decentralized (peer-to-peer) protocol that maintains a consistent view of active nodes in the presence of faults. Our protocol shows response time in the order of hundreds of microseconds and single-digit milliseconds for reconfiguration using MPI over BlueGene/L and TCP over Gigabit, respectively. The protocol can be adapted to match the network topology to further increase performance. We also verify experimental results against a performance model, which demonstrates the scalability of the approach. Hence, the membership service is suitable for deployment in the communication layer of MPI runtime systems.

Scalable, Fault-Tolerant Membership for Group Communication on HPC Systems

Biography

Jyothish Varma was born on the 3^{rd} of January 1983, in Kerala, India. He received his Bachelor of Technology in Computer Science from Model Engineering College, Cochin, India, in 2004. He opted to continue with his higher studies and joined North Carolina State University in Fall 2004. With the defense of this thesis, he is receiving the degree Master of Science in Computer Science from NCSU, in May 2006.

Acknowledgements

I would like to express my gratitude to the following people for their support and assistance in completing this thesis. To:

My advisor Dr. Frank Mueller. Without his guidance and support, I would not have been able to complete this project successfully. His willingness to clear any doubts, his insightful remarks, insistence on weekly reports, coding patterns and use of emacs were immensely helpful for the project to acquire its present form.

Dr. Vincent Freeh and Dr. Tao Xie for being on my advisory committee.

My friend and roommate Jaydeep Marathe. He was there with me always to provide help on any issues, for sharing ideas and providing me with an excellent work environment.

Last but not the least, all my lab mates of 324-A(MRC) and 3226(EB2) whose company I enjoyed during the completion of this project.

Chapter 1

Introduction

As contemporary high-performance computing (HPC) systems are increasing in size to thousands of processors, such as IBM's BlueGene/L (BG/L), high availability is becoming a challenge [2]. While the reliability of a single node is often remarkably high, a job's chance to complete execution prior to *any* failures decreases as the number of nodes to parallelize the job increases. For the BG/L at Livermore with 130k processors, a dual-processor compute card is currently failing every other day forcing a 1024-processor mid-plane to be temporarily shut down to replace the card [24]. In such large-scale environments, high-performance applications commonly employ a checkpoint-and-restart methodology to tolerate failures. When a node fails, the current job is generally relinquished in favor of a new job whose nodes restart from the last checkpoint saved on stable storage [39, 8, 9, 1]. Such application-side fault tolerance imposes the burden on the programmer to explicitly and non-portably address the robustness of the code for large HPC systems.

In this scenario, a scalable approach to reconfigure the communication infrastructure after node failures will have a significant impact on time that takes to re-start the application successfully. This thesis discusses the design, implementation and performance evaluation of a scalable, fault-tolerant membership algorithm for group communication on high performance computing systems.

1.1 Fault Tolerance - An Overview

A system can be said to be fault tolerant if it can continue its operations in the presence of failures of some of its components. This property is important in the case

of life-critical or high-availability systems. In a well designed system, component failure should only ideally lead to performance degradation. However, a poorly designed system can cause a total failure of the system even if a small component in the system fails. In the context of high performance computing, a system is a large cluster of nodes/processors[1], and components are the individual computing nodes. The lost availability of a system implies lost machine cycles. This makes the computation more expensive. As the scale of high performance computing systems increases, the failure rate also increases dramatically. The mean time between failures on such HPC systems is approximately 1-50 hours based on the extrapolation of existing machines [34]. This implies that more than 60% of the cycles (and investment) on the flagship supercomputers will be lost due to the overhead of dealing with reliability issues.

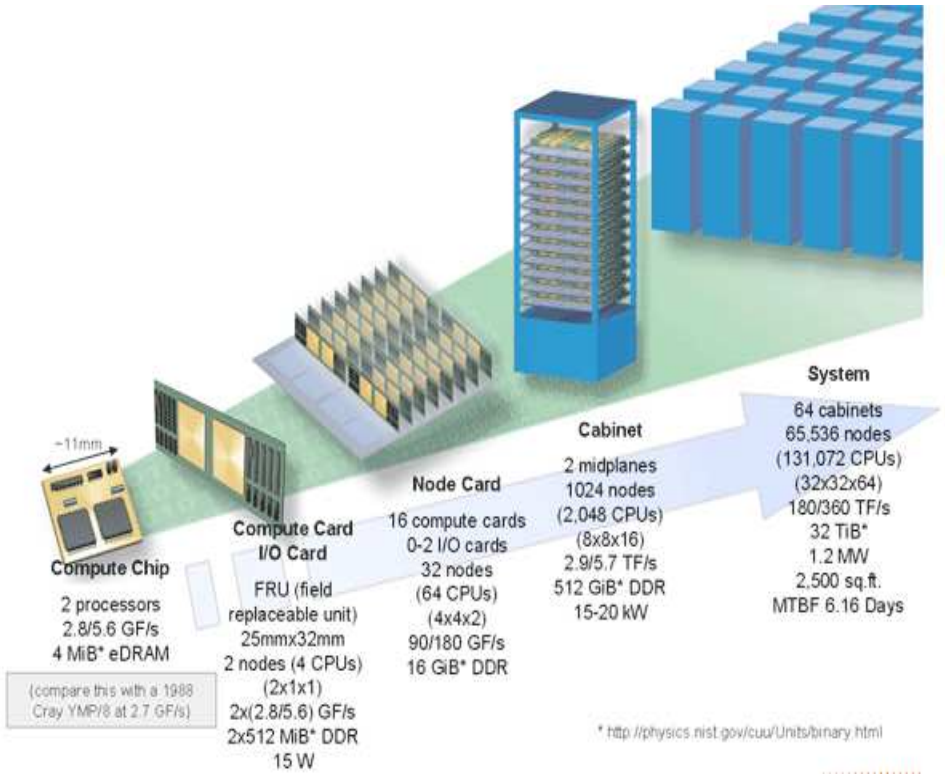

Figure 1.1: Blue Gene Architecture Overview

Figure 1.1 depicts the Blue Gene Architecture Overview [21] - one machine subject to frequent faults due to its size. Such systems with large numbers of processors pose new challenges such as hardware failure management, programming efficiency and scalability.

[1]The term nodes and processors are used inter-changeably. A node can be a single processor system or a multi-processor system.

Also, for these systems, the mean time between failures will be low. A study by Los Alamos National Laboratory extrapolates the mean time between failures on a petascale system to 1.25 hours based on current system performance [34]. If an application takes 100 hours without any fault for completion, it would take approximately 251 hours with faults due to checkpoint-restart overhead.

1.1.1 General Approach To Fault Tolerance

Different approaches to provide programmers with support for fault tolerance have been studied in the context of high-performance systems, ranging from application-level [18] over communication-level [38, 37, 16, 7] to network-level [4]. While application-side techniques require significant modifications to programs, they potentially reduce the amount of state that needs to be saved. These algorithms are highly applicable, but no concrete algorithm description has been proposed. New applications, methodologies and algorithms may be developed for improving performance and tolerating faults for future high performance machines at the application layer. An implementation at the communication layer provides a compromise in that modifications to the application are minimal and application state can be captured adequately. For example, the LAM/MPI Checkpoint/Restart Framework is transparent to the application and allows the system to be used for cluster maintenance and fault tolerance. Though the performance degradation caused by introducing this additional checkpoint/restart functionality in the MPI layer is negligible, the time to checkpoint increases linearly with the number of processes. Techniques at the network layer provide reliability within the message layer, but need to be complemented by additional techniques at higher abstraction levels.

1.1.2 Fault Tolerance in Large Systems

Efforts in group communication have focused on providing services to a dynamically growing and shrinking set of members (or nodes) [19, 3, 26, 30, 5]. These services are often Internet services using high-level communication abstractions. Implementations range from client-server approaches to the peer-to-peer paradigm with hybrids of both in the middle. These approaches generally utilize an all-to-all communication paradigm, which is inherently unscalable. More recent work on group membership proposes fully decentralized or hybrid approaches, but the resulting restructuring overhead is still in the order of

seconds [29, 42].

In this thesis, we contribute a scalable approach to reconfigure the communication infrastructure after node failures within the runtime system of the communication layer. In many of the current systems, the number of processors extends well beyond thousands. Current statistics [34] indicate that failures can be as frequent as one every two days on a HPC system. This imposes a high amount of reconfiguration and checkpoint/restart overhead and underlines the need for scalability in the algorithmic approaches that deal with fault tolerance.

1.2 Approach to Fault Tolerance

We propose a decentralized (peer-to-peer) protocol that maintains membership of MPI tasks in the presence of faults. This protocol is primarily tailored to local area networks, specifically dedicated clusters, instead of wide area networks or Grid frameworks.

However, while existing approaches provide either scalability or small reconfiguration overhead, our protocol combines these features. Instead of seconds for reconfiguration, our protocol shows overheads in the order of hundreds of microseconds and single-digit milliseconds over MPI on BG/L and TCP on Gigabit Ether, respectively. Our protocol can be configured to match the network topology to increase communication throughput. We utilize radix trees to implicitly encode routing information into node IDs and additionally represent the tree structure as an array (dynamically resized upon node joins/failures) to provide access to the data structure of individual nodes in constant time. We also verify our experimental results against a performance model to assess the scalability of the approach and allow extrapolation a for larger number of nodes.

Overall, our membership service for MPI tasks combines the best of both worlds, the scalability of a decentralized membership protocol and the performance of existing fault-tolerant mechanisms within high-performance runtime systems. This approach is more general and can be applied for any membership service or in other frameworks that require scalable group communication, such as efficient multicast services, *e.g.*, in MRNet [35].

1.3 Outline

The thesis is structured as follows. Chapter 2 presents an introduction to the membership problem, the assumptions of this work and discusses the detection of faults. Chapter 3 details the protocol actions in the presence of single and multiple faults. Chapter 4 describes a base performance model. Chapter 5 presents the experimental framework. Chapter 6 discusses functionality tests, experimental results and refines the performance models. Chapter 7 contrasts our work with related work. Chapter 8 summarizes the work.

Chapter 2

Assumptions and Fault Handling

To tolerate faults for an MPI job, the set of individual MPI tasks represents a group within which tasks may communicate and coordinate execution and termination. Within the runtime system, MPI tasks have a consistent *view* about who is a member in such an abstract communication domain [20, 6, 10]. Fault tolerance requires a dynamic domain in which members can join and leave. The latter may be due to faults while the former may occur upon recovery from faults or when additional compute resources are required. Group communication, such as multicasting, can be based on membership properties within a domain.

Membership within a domain is implemented within a runtime-level membership service layer and used by an application layer that relies on this service. The *view* of the system is the set of currently active and connected (unpartitioned) processes. The application layer interacts with the membership service for communication and *view change* actions. The membership service maintains a consistent view of the system. It ensures that communication takes place only between processes that share the same view. In our model, every process starts with a *default view*. This view is internally represented as a tree. In the absence of faults, each node has a children, where a is constrained to be a power of two for reasons given below.

2.1 Assumptions and Safety Properties

We make the following assumptions about the overall framework:

Execution Integrity: We assume that no event occurs at a process between its crash and recovery. After a crash, the process is assumed to remember its unique ID (*e.g.*, derived from the IP address or the host name), but not necessarily the view since a view may change any time. The new view is obtained from the current root on recovery.

Message uniqueness: Each message contains a message type, the sender and the receiver information. The underlying communication stack guarantees reliable messaging, *i.e.*, neither will there be any duplications nor losses of messages. Given message uniqueness, our protocol ensures that any message be sent exactly once to a given destination.

The protocol should meet the following safety properties of communication and multicast services (see [10, 14]):

Self Inclusion: The membership algorithm satisfies the self inclusion property, *i.e.*, if a process p establishes a view V, then p is a member of V. For every receive, there is a preceding send.

No duplication: At any process, two receive events can neither originate from the same send event, nor can they have identical message content.

Same view delivery: If two processes p and q receive message m, they receive it in the same view. The membership algorithm relies on the detection of faults by another layer of the software architecture. We specifically react to processor failures (crashes) and recoveries.

2.1.1 Fault Detection in the Execution Environment

Faults are detected by an external detection mechanism. Faults can be identified by hardware health monitoring, such as IPMI [22], detection of link failures or any other mechanism. The details are beyond the scope of this thesis.

For the experiments in section 6.1, we employ a fault detector based on a timeout mechanism. Excessive delay in response from any process to a message request leads to the assumption that the process has failed. Such a process is removed from the set of views in the *view change* event triggered by the above timeout. Link failures are handled similarly to node failures in this scenario, *i.e.*, different causes of failure need not be distinguished.

2.1.2 Processor Failure and Recovery

Within our execution environment, a fault-injecting application inquires the state of every other process randomly. This application is a micro-benchmark resembling the com-

munication portion of real applications communicating *via* MPI over a runtime-supported membership service. A failure should not cause the application to fail. Instead, each remaining node will update its membership view to obtain a new, consistent view in response to a message triggered within the tree structure excluding failed nodes.

Chapter 3

Group Membership Algorithm

In the following, the operational details of the membership algorithm, based on a radix tree, are detailed. The objective of the algorithm is to provide a new, consistent view of active nodes (members) in a scalable manner at very low overhead. The process of establishing a new view is called *tree stabilization* in the following.

3.1 Radix Tree Representation

Nodes participating in the membership service are internally represented in two data structures: a radix tree and a linear array of nodes. The former provides an efficient representation for collective communication while the latter supports point-to-point communication.

The radix tree provides a hierarchical representation that implicitly encodes routing information in the node ID, which reduces the overhead of algorithms that exploit the membership service. The radix encoding of a node ID can be used to determine the routing path of messages from the root to this node or to determine its position in the tree structure. To allow an efficient decoding of routing information, the number of children in the radix tree has to be a power of two. Hence, for a binary tree, the routing decision from one node to the next lower level is determined by a single bit indicating that one should follow the left (0) or right (1) child. In a tree with four children, such as in Figure 3.1, two bits indicate which link to follow to determine the location of a child in the tree.

In addition to the radix tree, an array of nodes provides access to arbitrary nodes at constant time, which can be utilized for point-to-point messages in a message-passing

framework. This array is dynamically resized upon node joins and failures to accurately reflect view changes in a consistent manner.

3.1.1 Initialization

At the initialization phase, every node in the system is assumed to have knowledge of the number of children and the total number of nodes. Each node has a unique ID. These assumptions are consistent with MPI runtime environments. Communication between nodes is not required during the initialization phase, since the knowledge of the number of children and the total number of nodes is sufficient for nodes to locally form a hierarchical structure.

The hierarchical structure, *i.e.*, the radix tree, is organized such that the node with lowest ID is the root. Each node has a fixed number of children. The ID of each child of a node is determined as a function of the height of the node in the tree and the maximum number of children, as depicted in Figure 3.1. This is a constant-time operation due to the routing information encoded into the radix tree.

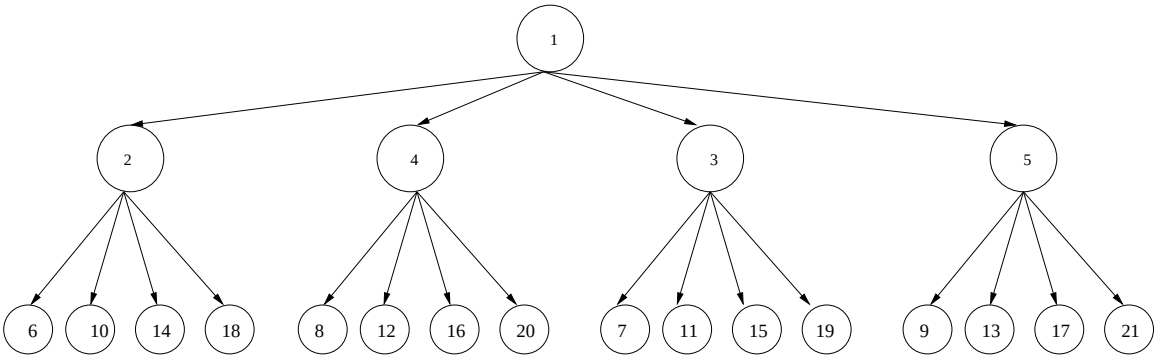

Figure 3.1: Stabilized Tree Structure

The radix tree is duplicated on each node and kept up-to-date with respect to a global view in a decentralized manner (consistent with other nodes). At startup, all nodes have the same initial view upon initialization. Afterwards, any two nodes in the application layer may communicate at any time. This approach still allows for node failures during start-up, as discussed later. Overall, the system is scalable due to the fully decentralized initialization since no message exchange is required to form the hierarchy. The tree structure with a configurable number of children furthermore ensures that the system can be adapted to reflect a given network topology.

3.1.2 Fault Handling

A node is considered to have failed if indicated by the failure detector. For the experiments in section 6.1, we detect a failure when a node does not respond within a timeout window to a query/message from another node. A node failure can be one of the following: Single node failure, multiple node failure, root failure and link failure. Upon detecting a failure, the root is informed of the failed node and initiates a view change (see Figure 3.3(a)).

A link failure is handled implicitly as if a node (and its subtree consisting of immediate children and their children etc.) is unreachable. Notice that partitions (subtrees) reorganize to form a new view (succinct from the view with the prior root). Applications may elect to continue or abort upon network partitioning, *e.g.*, depending on their ability to communicate with I/O nodes (such as in the BG/L model [2]).

3.1.3 Single Node Failure

This failure is the easiest to handle and requires very low communication bandwidth during the tree stabilization phase. The tree is assumed to be stabilized once the root receives an acknowledgment from all of its children affirming a stabilized tree in the lower layers, as depicted in Figure 3.3(a) and described below. Every failure detection message to the root will be acknowledged by a $FAILURE\_DET\_ACK$ message. When multiple nodes simultaneously detect the same failure, the root acknowledges each failure detection message but disregards all but the first failure detection messages.

For simulation purposes, our application scenario lets nodes inquire the state of other nodes in the system at random intervals. Assume that node 11 has sent a HOW_ARE_YOU message to a failed node 4 in Figure 3.1. On failure detection, it sends a $NODE\_FAILURE$ message to the root (assuming the failed node is not the root and all the nodes have a consistent view). The root recalculates its tree structure by eliminating the failed node from its list of nodes and updates corresponding links to its children in the tree, as depicted in Figure 3.2. The root node initiates the next step of the algorithm by sending a $FAILED\_NODE$ message to its children. Each child propagates the message down the tree after recalculating its local view (tree). The *flag* variable in the node failure algorithm can have 0 or 1 as its value and it indicates node failure and root failure respectively.

The local tree recalculation procedure is as follows. Let D be the failed node,

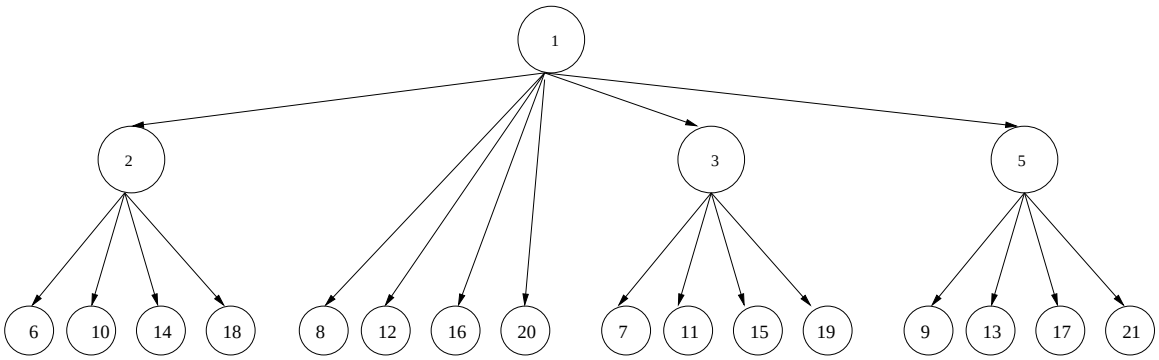

Figure 3.2: Tree Structure after node elimination

P(D) be its parent and C(D) the set of its children. Then, the new view is calculated by (1) assigning the parent of C(D) as P(D), (2) removing D from the list of children of P(D), (3) merging the list of children of D with the list of children of P(D) and (4) removing the list of children from D.

The tree structure will be consistent after each node has acknowledged to its parent a stable structure for the respective subtree. Once a $FAILED\_NODE$ message reaches a leaf node, the stabilization phase starts. Leaves respond with a $FAILURE\_ACK$ message to parents. Higher nodes acknowledge with a $FAILURE\_ACK$ to their parent once they have received the acknowledgments from their children. Failure to receive a $FAILURE\_ACK$ message will invoke another instance of the failure detector, as discussed in section 3.1.4. The tree becomes stable once the root receives a $FAILURE\_ACK$ from all children.

3.1.4 Multiple Node Failures

This case is handled similarly to a single node failure. If multiple nodes fail simultaneously, the root receives a $NODE\_FAILURE(X)$ message from the detector process while the first phase of tree stabilization is in progress. The root acknowledges each failure detection message, and, if multiple nodes detect a failure of the same node, all but the first message are disregarded (although acknowledged). For multiple, distinct failed nodes, the root sends a list of dead nodes after recalculating the tree locally. To facilitate the presentation, the list is omitted in Figure 3.3(a); it simply extends the `failed_node` parameter to a set. Example: Assume failures for nodes 4 and 5, and 11 has detected the failure of 4. The root sends $FAILED\_NODE(X)$ to its children and waits for an acknowledgment during the first tree stabilization phase. Since it does not receive an acknowledgment from

(a)**Handling a node failure**

On failure of a node (**ID**)
    if (ID == root)
        new_root = find_next_highest (ID);
        send $ROOT\_FAILURE$ (ID, self) message
        to new_root;
    else
        send $NODE\_FAILURE$ (ID, self) to root;

On receiving NODE_FAILURE(**failed_node**, **detector**)
by root
    send $FAILURE\_DET\_ACK$ to detector;
    Regroup (failed_node, flag);

Regroup(**failed_node**, **flag**)
    recalc_tree_structure(failed_node);
    locate my children;
    send $FAILED\_NODE$(failed_node) message to children;

On receiving FAILED_NODE(**failed_node**) **Message**
in a child
    if(self $\neq$ leafnode)
        Regroup(failed_node, flag);
        locate my children;
        send $FAILED\_NODE$(failed_node) message
        to children;
    else
        Regroup(failed_node, flag);

(b)**Handling a root failure**

On receiving ROOT_FAILURE(**ID**, **detector**)
by new_root
    send $FAILURE\_DET\_ACK$ to detector;
    Regroup(ID, flag);
Regroup(**failed_node**, **flag**)
    recalc_tree_structure(failed_node);
    locate my children;
    send $ROOT\_DEAD$ message to children;

(c)**Handling a node join**

On receiving NEW_NODE(**ID**) **by root**
    Regroup(new_node, flag);
    send $NEW\_NODE\_JOIN\_DET\_ACK$ to new_node;

Regroup(**new_node**, **flag**)
    recalc_tree_structure(new_node);
    locate my children;
    send NEW_NODE_JOIN message to children;

On receiving NODE_ALIVE(**ID**) **by root**
    Regroup(alive_node, flag);
    send $ALIVE\_NODE\_JOIN\_DET\_ACK$ to alive_node;

Regroup(**alive_node**, **flag**)
    recalc_tree_structure(alive_node);
    locate my children;
    send $ALIVE\_NODE\_JOIN$ message to children;

Figure 3.3: Pseudocode of the Membership Algorithm

node 5, it times out assuming that node 5 is dead. If this happens at lower layers of the tree, the node that fails to get an acknowledgment from the dead node informs the root through a $NODE\_FAILURE(Y)$ message. Then, the root propagates a list of failed nodes to its children. If a node failure has occurred at each level of the tree, it will take $H - 1$ initial tree stabilization phases for the tree to stabilize, where H is the tree height. A lower height can be achieved by choosing a larger number of children per node to speed up tree stabilization during multiple node failures. However, extremely low height (*e.g.*, a "flat" tree with just two levels) reduces performance as upper nodes become bottlenecks when propagating messages. Depending on the number of children (any power of two is legal), the height needs to be chosen accordingly, *i.e.*, by modeling stabilization time for different configurations.

3.1.5 Root Failure

Should the root fail, the detecting node sends a $ROOT\_FAILURE$ message to the next live node in the linear list (see Figure 3.3(b)), *i.e.*, a sequential scan suffices to designate a new root assuming the new root is alive. The algorithm proceeds in accordance with the single node failure recovery procedure explained above with following additions:

- The new root sends a $ROOT\_DEAD$ message to its children who transitively send it to their children.
- During the tree recalculation phase, each node also has to update its root to the new root.

The tree becomes stable after the new root has received acknowledgments from all of its children. Consider the case where a root failure coincides with multiple node failures. To distinguish this case for a single root failure, a different message, $ROOT\_AND\_NODE\_FAILURE$, will be propagated down the tree indicating the new root and the set of failed nodes, followed by acknowledgments upwards. This new message allows children of the failed nodes that may be engaged in recalculations due to a prior failure to identify its proper parent and acquire a consistent overall view. Due to the similarity to handling $FAILED\_NODE$ messages, this detail is omitted in Figure 3.3.

3.1.6 Node Join

A new node may join a domain (the set of MPI tasks) by sending a $NEW\_NODE(ID)$ message to the root (see Figure 3.3(c)). The root adds it as a leaf to the bottom of the tree. This message then propagates in the same way as for a node failure. The root issues a $NEW\_NODE\_JOIN(ID)$ message to its children, which is propagated further down the tree by its children. The tree assumes a stabilized structure once each node in the hierarchy has received $NEW\_NODE\_JOIN\_ACK(ID)$ from all of its children. The leaves will eventually send an acknowledgment to their respective parent, and this message is propagated upwards to the root. The *flag* variable in the node join algorithm can have 2 or 3 as its value and it indicates process recovering and new node join respectively.

An implicit node join may occur when a node recovers from a failure. Recovered nodes may re-join with their original ID by maintaining an association between host name and ID of failed nodes. This mapping is maintained by all the nodes in the system. The recovered process issues a $NODE\_ALIVE(ID)$ message to the root, and the stabilization routine follows the same procedure as for a join of a new node.

Once the tree is stabilized, the root sends $JOIN\_DET\_ACK$ message to the recovered process or the new node welcoming it to the system. A failure to get a $JOIN\_DET\_ACK$ from the root triggers the new node or a recovered process to send a $NEW\_NODE(ID)$ or $NODE\_ALIVE(ID)$ message, respectively, to the next node in its sequential list of nodes. The time to join the system might increase if a considerable number of processes have failed in the top of the hierarchy and a node with a lower ID has assumed the status of the root.

Chapter 4

Performance Modeling

In addition to the protocol design and implementation efforts, we attempted to model the performance of our protocol with a theoretical model. Initial efforts to measure the overall *time for stabilization*, Ts, in the presence of a single node failure within network simulators, such as the *network simulator 2* (Ns-2) [31], were considered inappropriate since such simulators generally do not allow computational overhead to be reflected in their models. We also observed practical challenges on clusters, as explained in the following, that cannot be accurately represented by simulation.

We derived a rudimentary performance model based on *communication overhead* (Ocm) and *computation overhead* (Ocp). Ocp captures the time for updating the tree structure on a local node and can simply be measured in wall-clock time on a target architecture. Ocm is based on the latency L of point-to-point connections of adjacent nodes in the tree.

Our *base model* assumes a single-hop connection between adjacent nodes with uniform latency measured as half the round-trip time in a ping-pong experiment. To measure Ocm for the entire tree, two times the latency is being considered between each node level, one per message, *i.e.*, to propagate a node failure down and another to receive a response. Let H be the height of the tree. Then, there are $H - 1$ levels for communication between parents and children. Thus,

$$Ocm = 2 \times L \times (H - 1) \tag{4.1}$$

The total tree stabilization overhead, Ts, is based on the overall communication overhead and the delay due to computational overhead within each level of the tree structure. Hence,

$$Ts = Ocm + Ocp * H \tag{4.2}$$

We next turn to experimental results to assess the performance of our protocol. The model is used as a reference to allow projections into larger number of processors if it fits the observed results. While found to be valid in principle, several refinements of the model were necessary due to machine-specific impacts on the latency, as discussed in the following. These refinements go beyond other models, such as LogP or its extensions [13].

Chapter 5

Experimental Framework

To assess the performance of our protocol, various tests were conducted on a number of test beds. We report the results for three of them in the following: a BlueGene/L (BG/L) machine, the OS cluster at North Carolina State University, and the eXtreme TORC (XTORC) cluster at Oak Ridge National Laboratory(ORNL). In the following, we discuss the interconnect in each test environment and the memory availability of each system.

5.1 Bluegene/L

On BG/L,all executables run on the compute nodes atop a light, UNIX-like proprietary kernel, the compute node kernel (CNK) [23]. There are two midplanes (each with 512 nodes or 1024 embedded PowerPC processors), and each midplane has a three-dimensional (3D) torus interconnect for point-to-point messages besides other interconnects for selected collective communication. When the partition is smaller than a midplane, the interconnect is a 3D mesh, hence, we ensured that an entire midplane was allocated to our jobs.

The memory requirement of the scheme is small and increases linearly with the number of nodes in the tree structure since each node keeps a copy of the tree. For BlueGene/L, each compute node has slightly less than 512MB of physical memory available for user programs. A tree structure that has 1024 nodes (using both midplanes of BlueGene/L) uses less than one MB of memory leaving ample memory space for the running applications. On BlueGene/L, MPI_Send and MPI_Irecv primitives implement the communication of the protocol. The reason for using non-blocking receive calls was to eliminate threading since (a) threading is not supported on BG/L and (b) threading was shown to result in high

overhead and variance in performance on Linux.

5.2 OS Cluster at NCSU

The OS Cluster runs Red Hat 7.3 Linux (kernel version 2.4.18) on a 16 node dual-processor AMD Athlon XP 1800+ machines connected by two switches, a full-duplex FastEther switch utilized through TCP/IP and a Myrinet switch using MPICH (v. 1.2.4) over Myrinet GM (v. 1.6.3). The OS cluster has 512 MB of physical memory per node of which only a negligible amount is used by the running program. A single threaded program model was used for the performance evaluation.

5.3 XTORC at Oak Ridge National Laboratory

XTORC has 64 2Ghz Pentium 4 compute nodes connected by 1Gb/s Ethernet running RedHat 9.0 (Linux kernel-2.4.20-8). Of the 64 nodes, only 47 nodes were available for testing. The entire test environment was written in C in a single-threaded manner since we observed high variations for threading in prior implementations.

XTORC provides 768MB of physical memory per node, and the memory requirement of our protocol was only a few kilobytes for less than 64 nodes. The implementation on XTORC relies on TCP sockets.

In all the above cases, a suggested improvement to limit the memory requirement to a constant size is to keep localized views of the overall tree structure. It will support scaling into tens of thousands of nodes and beyond and is subject to future work.

Chapter 6

Results and Performance Evaluation

The implementation of the protocol was subjected to extensive functionality tests with single node failures, multiple simultaneous failures, single root and chained, simultaneous root and top node failures, the last of which requires linear selection of the next root node. Failures were injected to the testing environment and resemble non-responsiveness of nodes as commonly detected by timeouts during communication.[1] The protocol proved to be robust to allow functioning nodes to survive failures of other nodes while still retaining the capability to communicate and track the set of operational nodes.

6.1 Performance Evaluation

We assessed the performance of our protocol in terms of the time for stabilization, Ts, after a single node failure, which is the most common type of failure since, as will be shown, Ts is in the order of hundreds of microseconds or single-digit milliseconds and, thus, orders of magnitude smaller than the mean-time-to-failure (MTTF) in even the largest systems. In the following discussion, a is the maximum number of children a parent node can have at each level of the tree structure.

[1] When a node times out but has not failed, it will still be treated as if it has failed since progress is hindered by this node. By excluding this node from further communication, other nodes can proceed in a timely manner, *e.g.*, by electing a replacement node within the MPI runtime system. Any messages from the excluded nodes pertaining to the old job are henceforth ignored by other nodes. If the node is fully responsive again, it may join the set of running nodes and can be assigned any work at that time, same as or different from the original work.

6.1.1 Experiments on BlueGene/L

Figure 6.1 depicts the experimental results for assessing the stabilization time, Ts, on BlueGene/L over MPI for increasing numbers of nodes. A binary tree configuration was chosen with two children (a=2). Notice that the x-axis is on a log scale, which shows that our protocol scales logarithmically with increasing number of nodes. Furthermore, Ts is in the order of microseconds up to 1024 nodes. If we interpolate these results, this trend is likely to continue into the tens of thousands of processors on BG/L. The results were obtained from five samples with a confidence interval of $\pm 3\mu$s to $\pm 16\mu$s for smaller and larger node numbers, respectively, at a 99% confidence level.

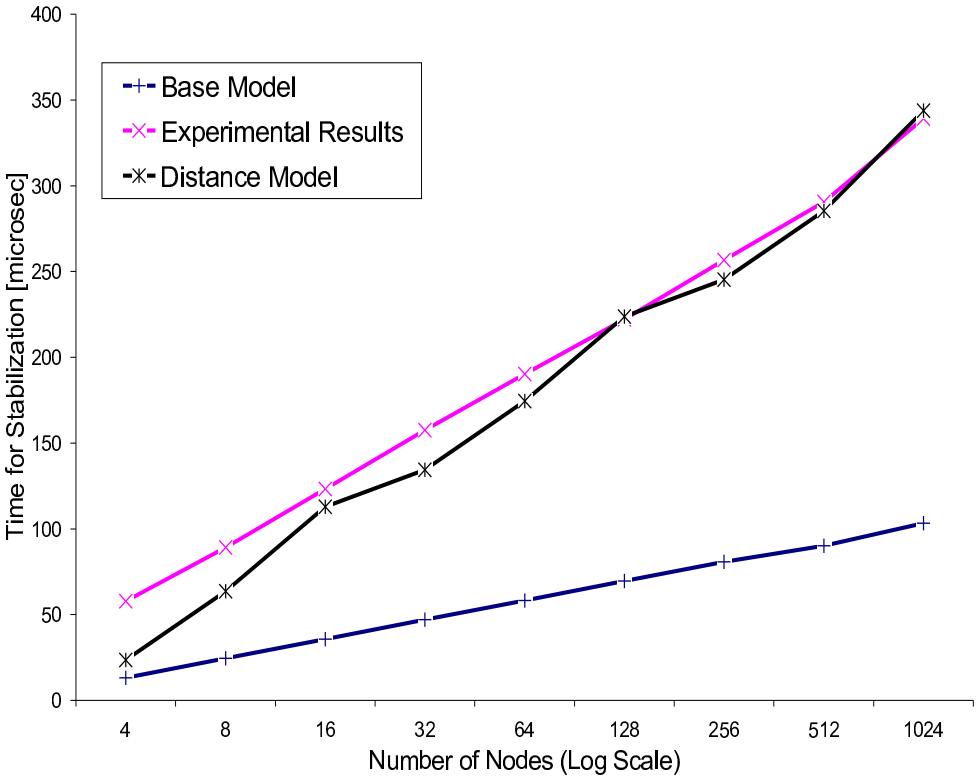

Figure 6.1: Ts over MPI for a=2 on BG/L

We also assessed the validity of our base model for a single hop, point-to-point latency of $L = 4.6\mu$s and a computational overhead of $Ocp = 2\mu$s on BG/L. The resulting base model diverges significantly from the experimentally obtained results. This can be attributed to the point-to-point communication topology of BG/L. We conducted our experiments on two midplanes with each midplane consisting of 512 processors, which have a 8x8x8 3D torus interconnect. When MPI tasks are mapped to nodes, adjacent nodes in

the tree may have to communicate over varying number of hop counts (distances) within the torus. Each hop thereby imposes the cost of the base latency L. To consider this overhead, we refined our base model to account for the communication overhead, Ocm, using a distance-aware latency to derive a *distance model*. Here, the overall number of hops contributing to the latency is the sum over all levels in the tree of the maximum distance in hops at each level. Thus,

$$Ocm = 2 \times \sum_{levels} max(\texttt{hops b/w nodes at level})] \times L \times (H-1) \tag{6.1}$$

This model considers the maximum latency between adjacent nodes (all parent/child pairs) at each level (in both directions) and aggregates the respective maximum for all levels in the tree. The hop count is determined as the sum of differences between each pair of x, y and z coordinates of nodes in the 3D-torus that are adjacent in the tree structure. As the results in Figure 6.1 show, this distance model closely matches the observed results. This underlines the benefits of simplicity and scalability of our protocol while delivering performance.

Figure 6.2 shows the stabilization time for a tree configuration with four children per parent (a=4). Again, the experimental results show that the protocol scales logarithmically with the number of nodes. The absolute overhead for Ts is slightly smaller than for the binary tree configuration (a=2), which can be attributed to the reduction of height in the tree. But the impact of hop counts reduces this benefit to some extent. The results were obtained from five samples with a confidence interval of $\pm 0.5\mu$s to $\pm 12\mu$s for smaller and larger node numbers, respectively, at a 99% confidence level.

The base model shows an interesting behavior in that it alternates between slight increases and no changes (flat line) in performance. A flat line occurs when the number of nodes is increased but the height of the tree remains unchanged, *i.e.*, the height of the tree changes only for powers of four. Once we consider the distance model that includes the hop counts for point-to-point communication in the tree, the model closely approximates the observed performance for each measurement point that is a power of four (or exceeds the height of the previous tree). In between, however, performance is underestimated. This artifact remains not fully explained, but we have eliminated system activity as a source. We will discuss network contention as a potential source in subsequent results. Nonetheless, the overall trends demonstrate the scalability of the protocol with a matching model for powers of four.

Notice that the protocol could alternatively have been implemented over the hard-

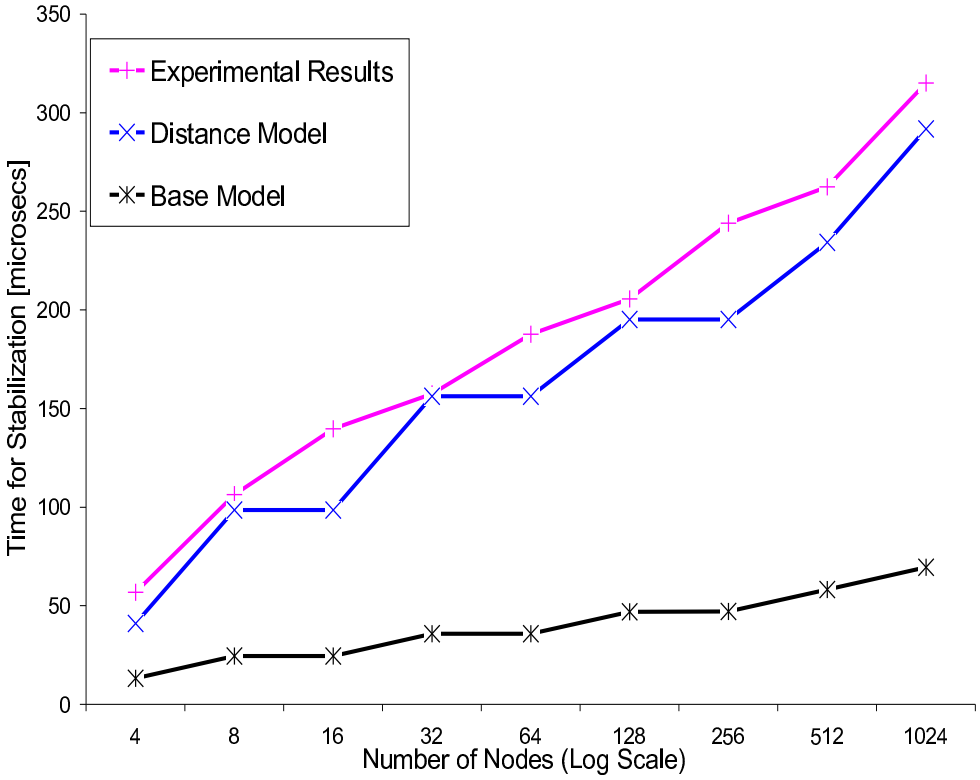

Figure 6.2: Ts over MPI for a=4 on BG/L

ware tree interconnect utilized by some collective communications on BG/L, which would have resulted in shorter response times. However, the objective of this work was to assess the scalability of the protocol for large numbers of nodes assuming commodity interconnect topologies without special one-to-all support in hardware.

6.1.2 Experiments on OS Cluster

The experiments on OS cluster are evaluated against the base model described in the Section 4 and a contention model is introduced in the following.

Using TCP over Ethernet

The stabilization time observed in the experiments on OS Cluster for a = 2 and a = 4 using TCP implementation of the protocol are shown in the Figures 6.3 and 6.4, respectively. The experimental results are evaluated against the base model and the contention model. The base model results are derived from Equation 4.2 using the point-to-point la-

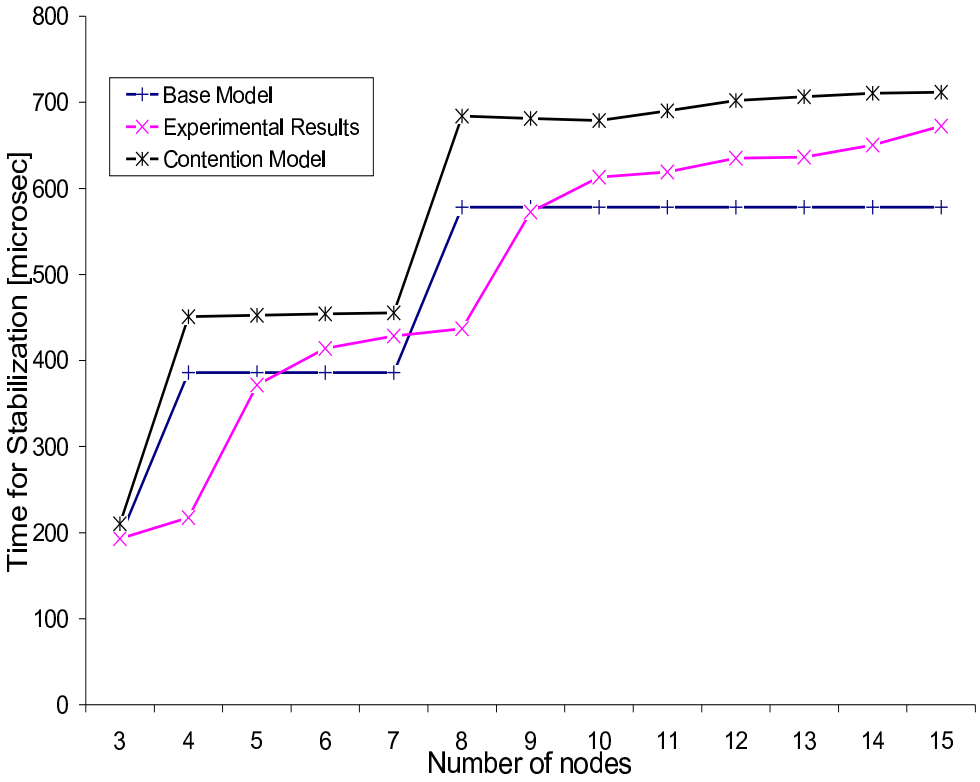

Figure 6.3: Stabilization Time (Ts), a=2 over TCP on OS Cluster

tency (TCP latency L = 94μs and computation overhead Ocm = 2.3μs) observed in the Figure 6.5. The experimental results in the Fig. 6.3 show a step-curve of increasing stabilization time. Also, Ts tends to increase linearly between any power-of-two node counts. The base model does not accurately reflect these experimental results as discussed in the following.

This linear increase in Ts can be attributed to packet serialization within the switch. The contention latency in the Figure 6.5 presents the latency under contention for a parent with two children (binary) and a parent with four children (4-ary) communicating with one another. The latency shows a steep climb till the number of nodes reaches 5 for a 4-ary tree and 3 for a binary tree. The latency values then shows a small increase with increasing number of nodes. These latency values are used in Equation 4.2 to obtain the contention model depicted in Figures 6.4 and 6.3. The results obtained from the contention-based model tends to resemble the experimental results observed for a fully-formed tree (*i.e,* at 3,7,15 nodes for a = 2 and 5,21 for a = 4). This indicates that substituting contention

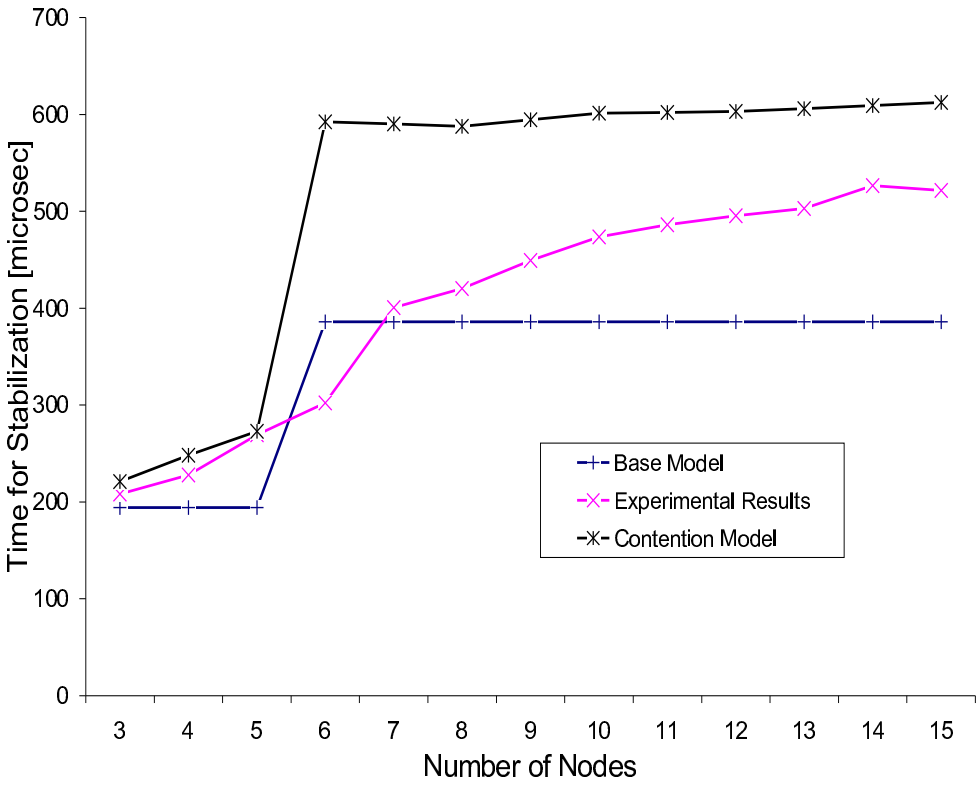

Figure 6.4: Stabilization Time (Ts), a=4 over TCP on OS Cluster

latency in the base model does not reflect the results obtained for a horizontal increase in the number of nodes within a level of the tree structure.

Using MPI over Myrinet

Figures 6.6 and 6.7 show the total time for tree stabilization as the number of nodes in the system is increased on the OS cluster using MPI. The latency for Myrinet was measured as 13.6 μsec. The results obtained for MPI over Myrinet are similar to the results discussed in Section 6.1.2. Equation 4.2 is used to compute the base model results. In the base model, depicted in the figures 6.6 and 6.7, as the height of the tree increases by one, the time for tree stabilization shows a significant rise and flattens out till the next level of the tree structure.

As the interconnection is a single full-duplex switch that allows direct communication between any pair of nodes, we do not consider hop counts as a factor for contention. The contention-based latency calculated for a fully-formed tree over MPI depicted in Fig-

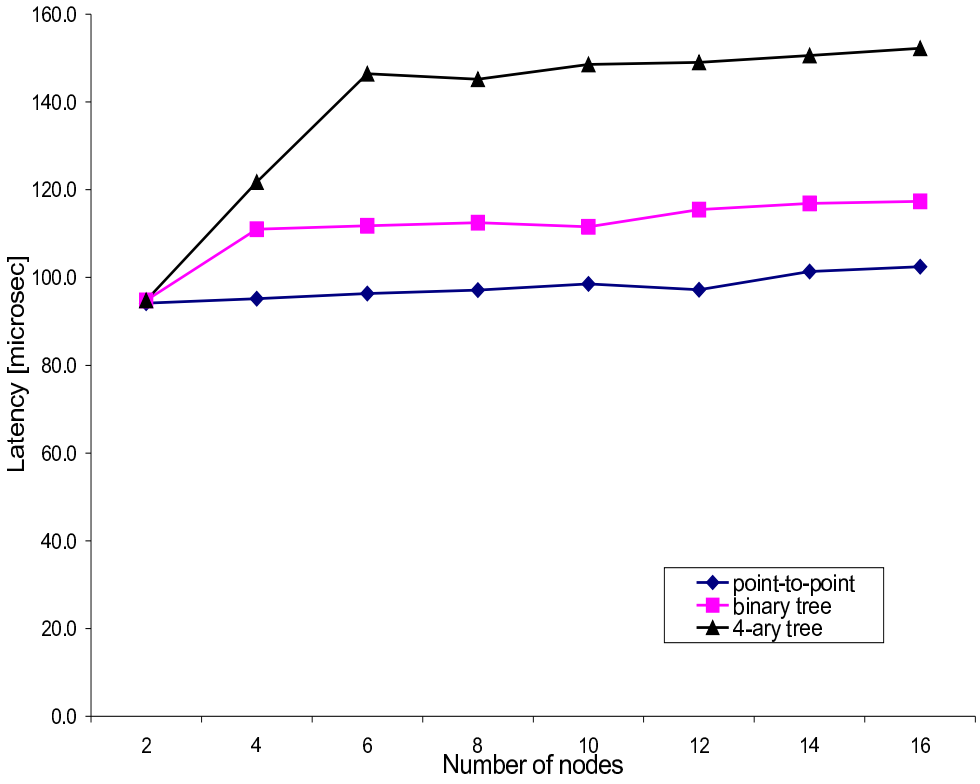

Figure 6.5: Contention-based Latency over TCP on OS Cluster

ure 6.8 remains a constant as the number of nodes increases. But the latency increases significantly when the number of children increases from two to four. This latency is used in Equation 4.2 to obtain the contention model of Figures 6.6 and 6.7. We observe that the experimental results matches the contention model for a fully formed tree structure. Here, the model does not match a horizontal increase in the number of nodes. We intend to investigate the causes of the linear increase in the stabilization time as the number of nodes increases in the same level of tree structure in future work.

6.1.3 Experiments on XTORC

Figure 6.9 depicts the stabilization time observed in experiments on a dedicated Linux cluster (no background activity) with a single Gigabit switch using a TCP implementation of our protocol for a binary tree (a=2). Notice that the x-axis is on a linear scale. The experimental results show a step-curve of increasing stabilization time. Upon closer analysis, we observe that the protocol is scalable for TCP as well, *i.e.*, that its time

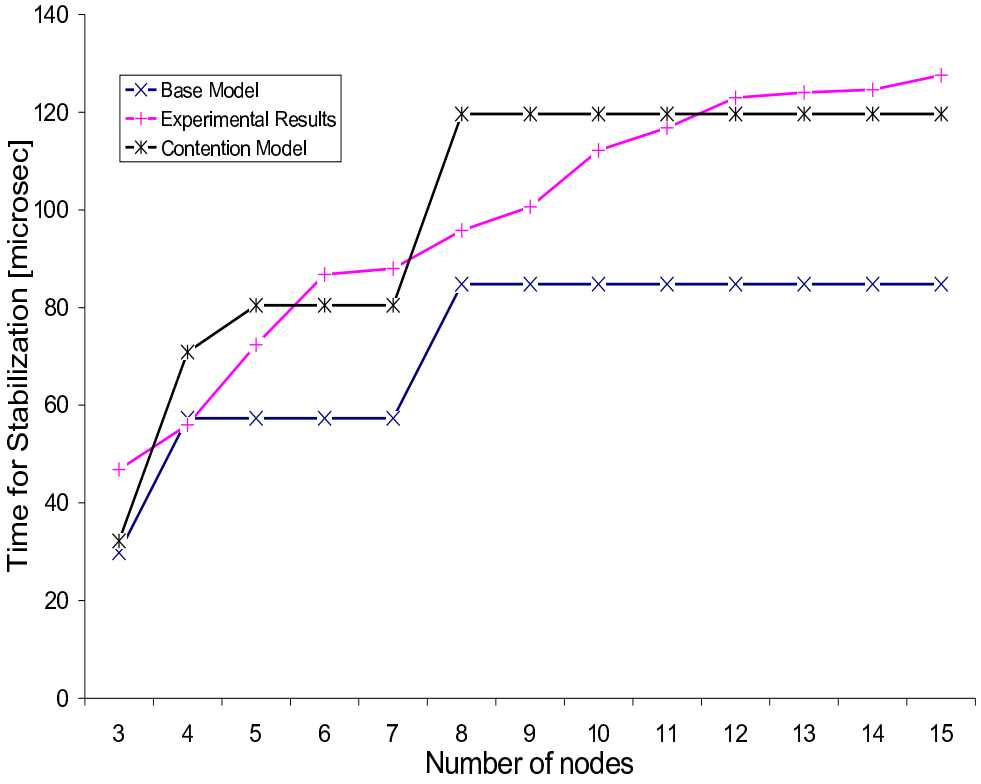

Figure 6.6: Stabilization Time (Ts), a=2 over MPI on OS Cluster

complexity increases logarithmically with the number of nodes.[2] The results were obtained from five samples with a confidence interval of $\pm 4\mu$s to $\pm 86\mu$s for smaller and larger node numbers, respectively, at a 99% confidence level.

We also observe that Ts increases linearly between any power-of-two node counts. This behavior is consistent with the experimental results in Figure 6.2. We further observe that the base model (with a TCP latency of $L = 118\mu$s and a computation overhead of $Ocm = 2\mu$s) does not resemble the experimental results. The hop count is not a factor as a single full-duplex switch allows direct communication between any pair of nodes without contention at the network fabric. The switch itself, however, may serialize packet processing.

The hypothesis of packet serialization within the switch was confirmed in a series of experiments where an increasing number of neighboring nodes communicated along a localized structure. Figure 6.10 presents the experimentally determined latency under contention for these configurations of (a) pairs of nodes, (b) a parent with two children

[2] A plot on a logarithmic x-axis for results of $2^n - 1$ nodes illustrates this behavior. The linear x-axis here is intentionally used to motivate the following analysis.

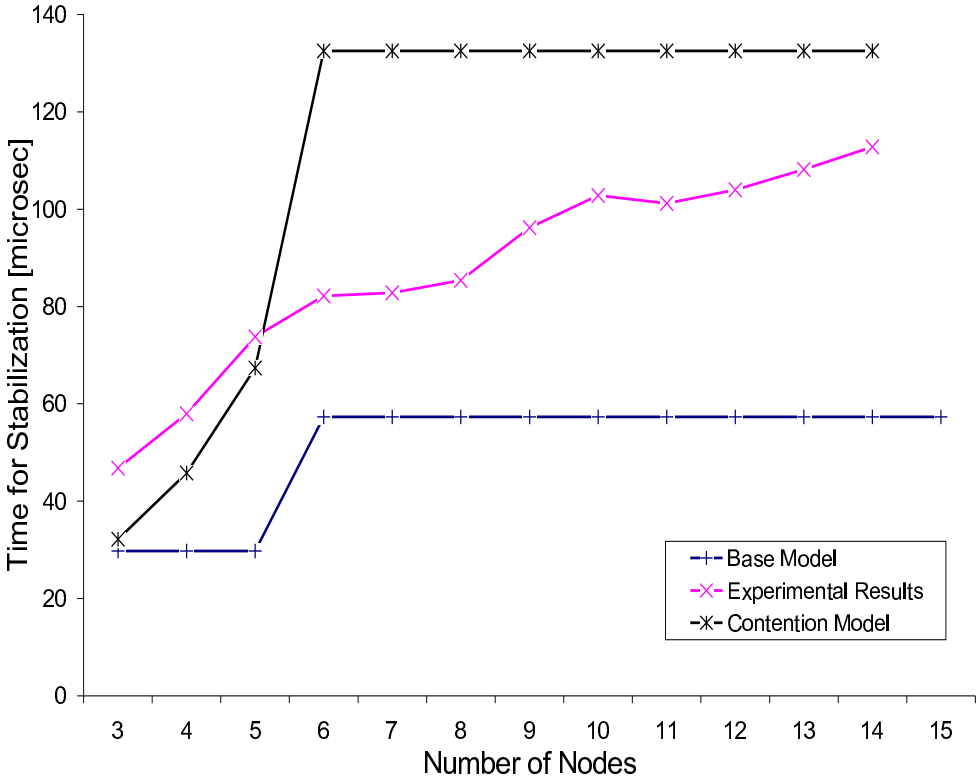

Figure 6.7: Stabilization Time (Ts), a=4 over MPI on OS Cluster

and (c) a parent with four children communicating with one another, as depicted in order of increasing latency. We observe that point-to-point communication of pairs of nodes is handled well by the switch up to twelve nodes, after which the latency linearly rises with the number of nodes added. More significantly, a more complex internal structure, such as a binary tree, inflicts higher switch contention for the same number of nodes due to serialized communication with multiple nodes at the parent. The latency increases even more significantly for a tree with four children.[3]

The results obtained as contention latency in Figure 6.10 were subsequently used to substitute the base latency in Equation 4.1 with the contention latency in the figure corresponding to the respective number of nodes. The resulting contention-based model in Figure 6.9 resembles the the experimental results very closely. Moreover, we argue that contention latencies can be extrapolated for larger node numbers, due to the near-linear

[3]Notice that these results could not be accurately be modeled by other models, such as LogP [12] with its account of send/receive overhead and the gap, since a linear increase with increasing number of nodes of any of the base parameters is not considered.

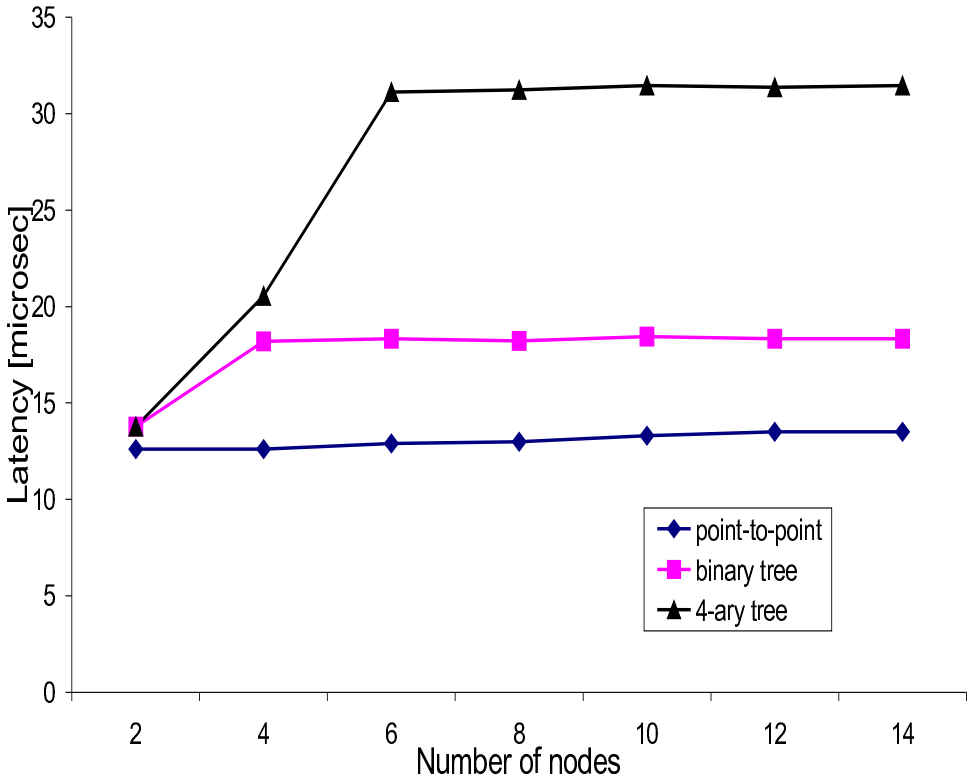

Figure 6.8: Contention-based Latency over MPI on OS Cluster

behavior in single switches. When switches are hierarchically combined, contention latencies of each single switch can be aggregated in a manner reflecting the switch topology. This is subject of future investigation.

Figure 6.11 depicts the results for TCP over a tree with four children per parent. The overall results indicate scalability of our protocol in terms of its logarithmic complexity. The results were obtained from five samples with a confidence interval of $\pm 12\mu$s to $\pm 98\mu$s for smaller and larger node numbers, respectively, at a 99% confidence level.

The base model shows the typical step curve with increases in stabilization time when the number of nodes increases such that the tree height increases by one (above 5 and 21 nodes), but the base model does not resemble the actual measurements. When considering the latencies of Figure 6.10, the contention model resembles the experimental results just before the tree hight is increased. More significantly, the contention model more accurately reflects the increased contention for larger number of nodes. The fact that the contention model tends to overestimate the experimental results is not fully understood

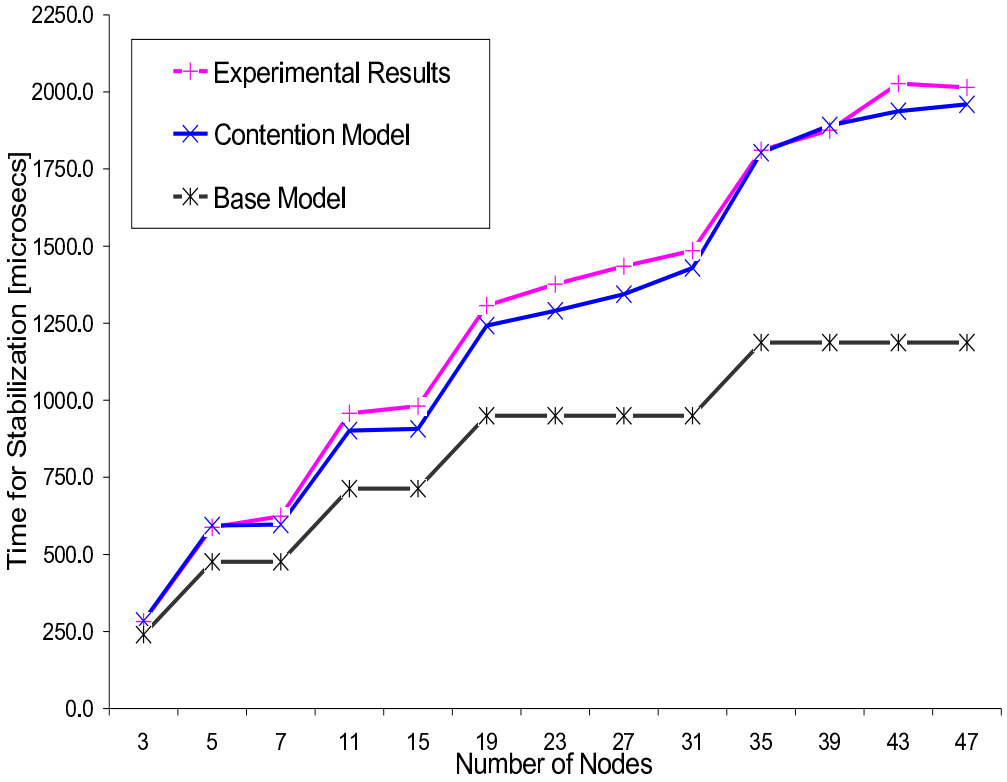

Figure 6.9: Ts over TCP for a=2 on XTORC

but we observed that larger overestimations also tend to coincide with larger confidence intervals.

Overall, the experimental results confirm the scalability of our protocol and the refined models show a close resemblance of experiments, which should qualify them for the task of extrapolations for larger number of nodes.

Chapter 7

Related Work

Chockler *et al.* provide a set of rigorous specifications for the group membership service and discuss various systems where different properties are satisfied [10]. Most of the existing systems assign a view identifier for each new view installed in the system [19, 3, 27]. Our model does not require to maintain a list of different views (*i.e.*, a view set with unique IDs per view) since the system stabilizes once the root node receives all acknowledgments from its children. Our approach of each process deciding its own view without exchange of any message with any other node is also found in Transis [30] and Consul [32]. We do not allow multiple disjoint views to exist concurrently. This property of primary component membership is implemented elsewhere as well [6, 40, 11]. A solution to the view-oriented partitionable membership problem is provided by R. Khazan [28, 29]. Their approach is a hybrid of decentralized clients and more powerful servers with a leader at any given point in time, *i.e.*, it is not a fully decentralized (peer-to-peer only) model due to practical network connectivity issues.

The Coyote system [5] provides a group membership service based on a token-passing paradigm and uses 25 micro-protocols to implement each group membership property. Our algorithm keeps the interaction among different nodes simple and stabilizes the hierarchical structure after each node receives just one message from its immediate parent node.

A topology-aware membership service for cluster-based Internet services is proposed by Zhou, Chu and Yang [41, 42]. It uses Time-To-Live in the IP packet header to form hierarchical groups that resemble the network topology. The reported time for tree stabilization for this model does not account for network latency, gap and over heads

involved for sending and receiving data. In this protocol, the view convergence time is measured as the sum of failure detection time and the time to propagate the information along the hierarchical tree. The paper does not provide the tree stabilization time. Hence, we cannot make a fair comparison with our work. Other prior work includes support for fault tolerance to the communication layer of MPI run time systems. Sankaran *et al.* [37] discuss a LAM/MPI checkpoint/restart framework where MPI applications can be check-pointed to disk and restarted later. They use the (Lawrence) Berkeley Labs Checkpoint/Restart (BLCR) mechanism [16, 17] to implement a lightweight and modular component-based architecture. It requires each MPI process to coordinate with other processes to reach a consistent global state in which the MPI job can be check-pointed. Bosilca *et al.* propose an uncoordinated checkpoint mechanism by saving the computation and communication contexts independently [7]. Each node stores the execution contexts in remote checkpoint servers and uses dedicated nodes (Channel Memory) to store in-transit messages.

Prior work on distributed locking explored the scalability of tree structures [15]. This prior work focused on mutual exclusion protocols and reader/writer locks in the context of middleware such as CORBA. A fault-tolerant extension of such a locking protocol is developed as a ring-based topology, which limits its scalability [33]. Our membership algorithm, in contrast, provides consistent views among nodes in the presence of faults in a scalable manner. Furthermore, the approach is reconfigurable for a variable number of children (as a power of 2), natively encodes routing information due to its use of a radix tree, and it provides constant time access to the data structure for individual nodes.

Chakravorty *et al.* [25] discuss a proactive fault tolerant mechanism for parallel applications. This approach is based on the assumption that some failures are predictable and specialized hardware mechanisms exist that help in early prediction of faults. They proactively migrate execution from a processor in which failure is imminent. Optimized efficiency is achieved by applying a load balancing scheme after migrating objects. They do not discuss how these mechanism respond to mis prediction of faults or systems that does not support early prediction of faults.

A leader-based group membership protocol is proposed by Chanchio *et al.* [36]. It does not depend any fault detection scheme and demands minimal fault detection support. The protocol responds by re-electing a new leader when the original leader process has failed. A number of event-based algorithms are used to resolve membership inconsistencies among asynchronous processes in a distributed environment. In this protocol, timing results

for recovering from a failure and regrouping a partition are extremely high and reach the order of minutes as the number of nodes increases.

Chapter 8

Conclusion

This work presents a novel membership algorithm that combines scalability with low recalculation overhead in the order of hundreds of micro-seconds and single-digit milliseconds for MPI over BG/L and TCP over Linux, respectively. The protocol supports reconfiguration in terms of the communication structure, *i.e.*, the data structures can be adapted to match the network topology to further increase performance. The protocol utilizes a radix tree representation to implicitly encode routing information into node IDs and additionally represent the tree structure as an array to provide access to the data structure of individual nodes in constant time. The protocol builds on prior experience of designing scalable communication frameworks by utilizing a fully decentralized protocol that maintains a coherent membership view of MPI tasks in the presence of faults. Experiments demonstrate high performance and scalability of our protocol over TCP on Gigabit Ether and over MPI on BG/L. Experimental results were also validated against a closely matching performance model to allow extrapolations to larger number of nodes.
